(54) **Codon optimized DNA sequence for insect toxin AaIT.**

(57) This invention provides for the construction of a codon optimized DNA sequence encoding the insect-specific toxin Androctonus australis insect toxin (AaIT). The codon optimized sequence is then inserted into an insect virus. A susceptible insect which ingests such a modified insect virus will cease feeding on plants due to a toxin-induced paralysis at an earlier time than an insect which ingests a wild-type insect virus lacking an AaIT gene.

EP 0 621 337 A1

Field of the Invention

This invention relates to the construction of a codon optimized DNA sequence encoding the insect-specific toxin AaIT, to the expression of that toxin, and the demonstration of in vivo toxicity of insect viruses
5   encoding that toxin.

Background of the Invention

The following abbreviations are used throughout this application:

10   A. cal. -   Autographa californica
       AcMNPV -   Autographa californica nuclear polyhedrosis virus
       AaIT -   Androctonus australis insect toxin
       bp -   base pairs
       CPU -   contractile paralysis unit
15   ECV -   extracellular virus
       GV -   granulosis virus
       kD -   kilodaltons
       LT -   lethality time
       MOI -   multiplicity of infection
20   NPV -   nuclear polyhedrosis virus
       OB -   occlusion body
       Occ- -   occlusion negative virus(es)
       Occ + -   occlusion positive virus(es)
       PCR -   polymerase chain reaction
25   PDV -   polyhedron derived virus
       PFU -   plaque forming unit
       p.i. -   post-infection
       PIB -   polyhedron inclusion body (also known as OB)
       ST -   survival time
30   The family of DNA insect viruses known as Baculoviridae includes nuclear polyhedrosis viruses (NPV)
and granulosis viruses (GV). These viruses produce occlusion bodies (OBs) in their life cycle. Also included
are the non-occluded viruses (NOV), which do not produce OBs in their life cycle. Another family of DNA
insect viruses are the entomopox viruses.
       Over 400 baculoviruses have been identified as present in invertebrates. Examples of NPVs include
35   Lymantria dispar NPV (gypsy moth NPV), Autographa californica MNPV, Syngrapha falcifera NPV (celery
looper NPV), Spodoptera litturalis NPV, Spodoptera frugiperda NPV, Heliothis armigera NPV, Mamestra
brassicae NPV, Choristoneura fumiferana NPV, Trichoplusia ni NPV, Helicoverpa zea NPV, etc. Examples of
GVs include Cydia pomonella GV (codling moth GV), Pieris brassicae GV, Trichoplusia ni GV, etc.
Examples of NOVs are Orcytes rhinoceros NOV and Heliothis zea NOV. Examples of entomopox viruses
40   include Melolontha melonotha EPV, Amsacta moorei EPV, Locusta migratoria EPV, Melanoplus sanguinipes
EPV, Schistocerca gregaria EPV, Aedes aegypti EPV, Chironomus luridus EPV, etc.
       The use of baculoviruses and entomopox viruses as bioinsecticides holds great promise. One of the
major impediments to their widespread use in agriculture is the time lag between initial infection of the
insect and its death. This lag can range from a few days to several weeks. During this lag, the insect
45   continues to feed, causing further damage to the plant. A number of researchers have attempted to
overcome this drawback by inserting a heterologous gene into the viral genome, so as to express an insect
controlling or modifying substance, such as a toxin (Bibliography entries 1,2,3).
       The life cycle of baculoviruses, as exemplified by AcMNPV, includes two stages. Each stage of the life
cycle is represented by a specific form of the virus: Extracellular viral particles (ECV) which are
50   nonoccluded, and occluded virus particles (OB) (4,5). The extracellular and occluded virus forms have the
same genome, but exhibit different biological properties. The maturation of each of the two forms of the
virus is directed by overlapping sets of viral genes, some of which are unique to each form.
       In its naturally occurring insect infectious form, multiple virions are found embedded in a paracrystalline
protein matrix known as an occlusion body (OB), which is also referred to as a polyhedron inclusion body
55   (PIB). The proteinaceous viral occlusions are referred to as polyhedra (polyhedron is the singular term). A
polyhedrin protein, which has a molecular weight of 29 kD, is the major viral-encoded structural protein of
the viral occlusions (4,6). (Similarly, GVs produce OBs which are composed primarily of granulin, rather
than polyhedrin).

species (but not vertebrates) and causes paralysis and ultimately death of the insect.

The insertion of the gene encoding AaIT into a baculovirus results in the expression of the toxin. A susceptible insect which ingests such a modified baculovirus will cease feeding on plants due to a toxin-induced paralysis at an earlier time than an insect which ingests a wild-type baculovirus lacking an AaIT gene. The greater the reduction in time, the greater the reduction of damage to crops, because the period of larval feeding is reduced. Thus, this invention provides a method for protecting plants from damage from insects, by delivering to the plant (through spraying or other delivery means) an expression vector incorporating this codon optimized nucleic acid sequence for producing AaIT.

The degeneracy of the genetic code permits variations of the nucleotide sequence, while still producing a polypeptide having the identical amino acid sequence as the polypeptide encoded by the native DNA sequence.

The frequency of individual synonymous codons for cognate amino acids varies widely from genome to genome among eucaryotes and procaryotes. These differences in codon choice patterns appear to contribute to the overall expression levels of individual genes by modulating peptide elongation rates.

The invention involves the design of an AaIT gene for use in a baculovirus expression system. It is first attempted to have the preferred codon usage frequencies for this synthetic gene reflect the codon usages of genes derived from the genome of the cell/organism to be used for recombinant protein expression. However, adequate representation for both lepidopteran gene sequences and insect viral gene sequences was not available at the time of this invention to create a reliable codon usage table, because there was DNA sequence information available from only a small number of genes.

Therefore, codon use tables are taken from a species, Drosophila melanogaster, which has a sufficient number (at least 10) of known gene sequences. These codon use tables are used to design the codon optimized gene encoding AaIT. This methodology also permits the preservation or destruction (if desired) of restriction enzyme recognition sites. The codon use frequency for each amino acid of AaIT reflects frequencies in Drosophila melanogaster codon use tables.

The codon optimized gene encoding AaIT of this invention has the sequence of 210 nucleotides set forth in SEQ ID NO: 3. This sequence differs from that of the wild-type (native) AaIT gene sequence (SEQ ID NO: 1) in 58 out of 210 nucleotides (see Figure 1).

Brief Description of the Drawings

Figure 1 depicts a comparison of the nucleotide sequences of of native and codon optimized genes encoding AaIT, together with the amino acid sequence of AaIT.

Figure 2 depicts detail of the construction of the plasmid pBS Cuticle-AaIT, which contains the heterologous cuticle signal sequence and a codon optimized cDNA sequence encoding AaIT.

Figure 3 depicts detail of the construction of the plasmid pBS GIII-AaIT, which contains the native signal sequence and the native cDNA sequence encoding AaIT.

Figure 4 depicts the levels of toxin-encoding RNA as a percentage of polyhedrin RNA which accumulates in Sf9 cells infected with wild-type AcMNPV. A DNA probe detects the 3' untranslated region common to both toxin and polyhedrin RNAs. The bars on the X axis are as follows: Mock (non-infected); Wild Type (wild-type AcMNPV); Es6-AaIT (AcMNPV containing esterase-6 signal sequence and codon optimized AaIT gene); ADK-AaIT (AcMNPV containing adipokinetic signal sequence and codon optimized AaIT gene); Cut-AaIT (AcMNPV containing cuticle signal sequence and codon optimized AaIT gene); pBM-AaIT (AcMNPV containing pBMHPC-12 signal sequence and codon optimized AaIT gene); Chor-AaIT (AcMNPV containing Chorion signal sequence and codon optimized AaIT gene); Apo-AaIT (AcMNPV containing apolipophorin signal sequence and codon optimized AaIT gene); Sex-AaIT (AcMNPV containing sex specific signal sequence and codon optimized AaIT gene); and grp III-AaIT (AcMNPV containing native signal sequence and native AaIT gene).

Figure 5 depicts graphs of the response time of H. virescens larvae in a viral injection assay. In Panel A, larvae receive either no virus (negative control)(80 insects) or 100, 1000 or 10,000 PFU of wild-type AcMNPV (Strain E2)(48 insects each). In Panel B, larvae receive either no virus (negative control)(80 insects) or 100, 1000 or 10,000 PFU of AcMNPV which contains the cuticle signal sequence and a codon optimized cDNA encoding AaIT (48 insects each).

Figures 6-15 depict graphs of the oral toxicity of viruses, presented as a percentage of larvae responding at various time intervals to the indicated doses of virus present in a microdrop of ingested diet. Figure 6 depicts wild-type AcMNPV (Strain E2), which is used as a control for Figures 7-10. Figure 7 depicts an esterase-6-AaIT-virus construct. Figur 8 depicts an adipokinetic hormone-AaIT-virus construct. Figure 9 depicts a cuticle-AaIT-virus construct. Figure 10 depicts the native signal-native AaIT-virus

construct. Figure 11 depicts wild-type AcMNPV (Strain E2), which is used as a control for Figures 12-15. Figure 12 depicts a pBMHPC-12-AaIT-virus construct. Figure 13 depicts a chorion-AaIT-virus construct. Figure 14 depicts an apolipophorin-AaIT-virus construct. Figure 15 depicts a sex specific-AaIT-virus construct. The constructs in Figures 7-9 and 12-15 include a codon optimized AaIT gene.

Detailed Description of the Invention

The present invention provides for the construction of a codon optimized DNA sequence encoding the insect-specific toxin AaIT. This isolated nucleic acid sequence is then inserted into an expression vector which is appropriate for the host cell or organism in which the toxin is to be produced. This toxin has the same amino acid sequence as native AaIT. The DNA sequence can be inserted directly into the expression vector or can be inserted with the aid of a transfer vector.

The insertion of the gene encoding AaIT into an insect virus results in the expression of the toxin, which is responsible for a reduction in the time needed for the virus to incapacitate and kill larvae. A susceptible insect which ingests such a modified insect virus will cease feeding on plants at an earlier time than an insect which ingests a wild-type insect virus lacking an AaIT gene. The greater the reduction in time, the greater the reduction of damage to crops, because the period of larval feeding is reduced.

The degeneracy of the genetic code permits variations of the nucleotide sequence, while still producing a polypeptide having the identical amino acid sequence as the polypeptide encoded by the native DNA sequence. The procedure known as codon optimization provides one with a means of designing such an altered DNA sequence.

The design of codon optimized genes should take into account a variety of factors, including the frequency of codon usage in an organism, nearest neighbor frequencies, RNA stability, the potential for secondary structure formation, the route of synthesis and the intended future DNA manipulations of that gene.

The degeneracy of the genetic code permits the same amino acid sequence to be encoded and translated in many different ways. For example, leucine, serine and arginine are each encoded by six different codons, while valine, proline, threonine, alanine and glycine are each encoded by four different codons.

However, the frequency of use of such synonymous codons varies from genome to genome among eucaryotes and procaryotes. For example, synonymous codon-choice patterns among mammals are very similar, while evolutionarily distant organisms such as yeast (S. cerevisiae), bacteria (such as E. coli) and insects (such as D. melanogaster) reveal a clearly different pattern of genomic codon use frequencies (8-13).

These differences in codon-choice patterns appear to contribute to the overall expression levels of individual genes by modulating peptide elongation rates. Two lines of experimental evidence support this argument. First, the rate of polypeptide synthesis depends on the character of the codons being translated, as well as the initial kinetics for transfer RNA ("tRNA") ternary complex formation (13-18). Second, cellular transfer RNA distributions tend to follow the cognate codon frequencies of the messenger RNA ("mRNA") pool (18-21).

For these reasons, it is desirable and useful to design genes intended for insect virus expression systems where the codon frequencies reflect the cognate cellular tRNA frequencies. This is particularly desirable for expression systems like the baculovirus expression system using the polyhedrin promoter, where a single mRNA specie may utilize over one-half the cellular translation capacity. Hence, codon frequency really should reflect the cognate cellular tRNA frequencies when expressing recombinant protein at high levels.

The preferred codon usage frequencies for a synthetic gene should reflect the codon usages of nuclear genes derived from the exact (or as closely related as possible) genome of the cell/organism that is intended to be used for recombinant protein expression.

In the present invention, adequate representation for both lepidopteran gene sequences and insect viral gene sequences was not available to create a reliable codon usage table for these initial experiments.

For example, for the design of the AaIT gene, there was at the time of this invention DNA sequence information from only two specialized proteins: AcMNPV polyhedrin and AcMNPV p10 (22,23). Ikemura et al. have cautioned that reliable codon-choice patterns require the summation of codon frequencies from ten or more genes with varying functions (10,24). This codon optimized sequence is intended to be expressed in a variety of insects, not just those infected by AcMNPV. Therefore, it is of primary importance that the codon optimization be compatible with the tRNA pool distribution in a variety of insect cells.

For this reason, an insect specie is selected which has a sufficient number of known gene sequenc s. Drosophila melanogaster has codon use tables derived from 44 nuclear genes totalling 20,451 codons (11). These codon use tables are used to design the codon optimized genes encoding signal sequences and the AaIT toxin sequence of this invention.

5   A gene for a full length signal peptide sequence is fused to the codon optimized AaIT toxin peptide sequence. As discussed in detail below, the signal sequence may be the AaIT signal sequence or a native or codon optimized nucleotide sequence encoding a heterologous signal sequence.

These amino acid sequences are reverse-translated into a DNA sequence showing all possible nucleotide degeneracies (maximum ambiguity). A list of definite and potential (because of codon degen-
10   eracies) restriction enzyme recognition sites is generated. Restriction enzyme sites critical for gene synthesis as well as for the convenience of additional DNA manipulation are selected and preserved. One important advantage of assigning codons during the design of optimized genes is that restriction enzyme sites can be readily preserved or destroyed at the convenience of one skilled in the art to facilitate gene contruction and manipulation.

15   A list recording the number of times each amino acid occurs in AaIT and each signal sequence is generated. Codons are assigned on the basis of the number of amino acid residues present in the sequence to reflect the relative frequency of Drosophila melanogaster codon use (11).

For example, the cysteine codon frequency in Drosophila melanogaster is 76% for the sequence TGC and 24% for the sequence TGT. There are eight cysteine residues in the ADK signal-AaIT gene construct
20   (all in the gene coding for the mature AaIT protein (SEQ ID NO: 3)). Hence, six codons are allocated as TGC (75% of the residues) and two codons as TGT (25% of the residues). Based on this distribution, each cysteine codon is then assigned an exact, unambiguous sequence. Attention is given to alternating adjacent isocodons. For example, the two adjacent cysteine residues in the AaIT peptide (amino acids 37 and 38) are assigned the sequence TGT TGC to avoid assigning two identical codon sequences sequentially.

25   This process is repeated for all twenty amino acids and the termination codon (although the termination codon sequence TAA is not changed by this procedure). In addition, all critical restriction enzyme sites are preserved and unwanted sites are destroyed.

The codon optimized nucleic acid sequence of this invention is synthesized and assembled using conventional techniques. Example 2 below describes one such method using a series of synthetic
30   oligonucleotide fragments which are then joined to form the complete coding sequence.

The complete codon optimized sequence of this invention (SEQ ID NO: 3) differs from the native cDNA sequence encoding AaIT (SEQ ID NO: 1) by 58 out of 210 nucleotides (see Figure 1). However, the AaIT produced by the native cDNA and the codon optimized cDNA have identical amino acid sequences. If desired, the signal sequence for AaIT may also be codon optimized by the same procedures just described.

35   Once the synthetic gene containing the codon optimized nucleic acid sequence is constructed, the gene is inserted into an appropriate expression vector, by conventional techniques such as cloning into the vector after digestion with one or more appropriate restriction enzymes. Smith and Summers United States Patent 4,745,051 (6) describes the construction of baculovirus expression vectors, which are recombinant insect viruses in which the coding sequence for a foreign gene is inserted behind a baculovirus promoter in
40   place of the viral polyhedrin gene. The polyhedrin gene is nonessential for productive viral infection between cells.

Transfer vectors are used as tools to transfer foreign genes into a viral genome. Transfer vectors generally are bacterial plasmids containing sufficient viral sequences to facilitate insertion of the foreign gene into the viral genome by homologous recombination.

45   Methods for constructing recombinant baculoviruses in cultured cells are set forth in M. D. Summers and G. E. Smith, A Manual of Methods for Baculovirus Vectors and Insect Cell Culture Procedures, Texas Agricultural Experimental Station Bull. No. 1555 (1987) (25). A preferred cell line is that of Sf9 cells (ATCC accession number CRL1711), which are derivatives of the cell line designated Spodoptera frugiperda 21 (Sf21). Other insect cell lines that are adequate for propagation of a desirable insect virus include those
50   derived from Trichoplusia ni (TN368), the silkworm Bombyx mori (BM) and Helicoverpa zea (BCIRL-Hz-Am1, BCIRL-Hz-Am3).

Suitable insect viruses include those listed above in the Background of the Invention. A preferred insect virus is the baculovirus AcMNPV. A particular strain of AcMNPV designat d E2 is used in the Exampl s. Those of skill in the art will recognize that other baculovirus strains may also be used. These include
55   Trichoplusia ni MNPV, Rachiplusia ou MNPV, Galleria mallonella MNPV, Spodoptera frugiperda NPV and plaque-purified strains such as the M3, R9, S1 and S3 strains of AcMNPV isolated and characterized in Smith, G.E., and Summers, M.D., J. Virol., 33, 311-319 (1980) (26), as well as Bombyx mori NPV. See also Smith, G.E., and Summers, M.D., Virol., 89, 517-527 (1978) (27).

As described above, the expression of AaIT by an insect virus reduces the time needed to incapacitate a larva. In turn, the maturation and secretion of functional toxin is facilitated by a signal peptide.

Signal sequences are required for a complex series of post-translational processing steps which result in secretion of a protein. If an intact signal sequence is present, the protein being expressed enters the lumen of the rough endoplasmic reticulum and is then transported through the Golgi apparatus to secretory vesicles and is finally transported out of the cell. Generally, the signal sequence immediately follows the initiation codon and encodes a signal peptide at the amino-terminal end of the protein to be secreted. In most cases, the signal sequence is cleaved off by a specific protease, called a signal peptidase. Preferred signal sequences improve the processing and export efficiency of recombinant protein expression using viral expression vectors. Optimized expression of the toxin using an appropriate heterologous signal sequence achieves more rapid lethality than wild-type insect virus.

Summers United States Patent 5,155,037 (28) describes the use of insect signal sequences such as adipokinetic hormone and cuticle in a Lepidopteran insect cell transformed or transfected with a DNA vector, where said signal directs the secretion of a heterologous protein from the insect cell. The only foreign proteins disclosed are CD4, interleukin-2 and beta-interferon. All of these proteins are mammalian proteins; none is an insect toxin. Prior to United States Patent 5,155,037, the only method of achieving secretion of a foreign protein in insect cells is by using the foreign gene's native signal peptide. Because the foreign genes are usually from non-insects, their signals may be poorly recognized by insect cells, resulting in suboptimal levels of expression. The signal sequence is generally coded by a DNA sequence immediately following (5' to 3') the translation start site of the foreign gene. Proteins secreted from cells are synthesized as precursor molecules containing hydrophobic N-terminal signal peptides.

A secretory signal sequence contains three regions: A basic N-terminal region (n-region); a central hydrophobic region (h-region); and a more polar C-terminal region (c-region) (29). Cleavage of the signal sequence from the mature protein once export is under way appears to be dependent upon structures in the n- and h- regions; however, positions -3 and -1 relative to the cleavage site (in the c- region) have been suggested to be the most important (29). The residue in position -1 should be small (alanine, serine, glycine, cysteine, threonine or glutamine), while the residue in position -3 should not be aromatic (phenylalanine, histidine, tyrosine or tryptophan), charged (asparagine, glutamic acid, lysine or arginine) or large and polar (asparagine or glutamine), with proline being absent from the region -3 to +1. Some exceptions to these parameters are permitted (29).

This -3, -1 rule is 75-80% predictive of the cleavage site in mammalian systems (29), but has not been confirmed in insect systems.

Summers United States Patent 5,155,037 (28) describes the sequence encoding the Lepidopteran (Manduca sexta) adipokinetic hormone signal peptide. This is a short signal peptide (19 amino acids) for a blocked neuropeptide that regulates energy substrate mobilization and metabolism in insects. Figure 2B of the patent depicts the nucleotide and amino acid sequences of the signal peptide.

The patent also describes the sequence encoding Drosophila melanogaster cuticle signal peptide. Figure 2A of the patent depicts the nucleotide and amino acid sequences of the cuticle gene CP1 leader peptide. The nucleotide sequence codes for a 16 amino acid signal peptide.

In an effort to identify heterologous signal sequences useful with the codon optimized AaIT gene, eight constructs with heterologous signal sequences are prepared by Applicants. The DNA sequences encoding these signal sequences can be either the native DNA sequences encoding the signal sequences or the codon optimized DNA sequences encoding those signal sequences.

These signal sequences are then combined with the codon optimized AaIT gene described previously in Bluescript plasmids (Stratagene, LaJolla, CA). Each such gene is inserted into a baculovirus transfer vector and then moved into the AcMNPV genome by homologous DNA recombination in cultured cells (25). The heterologous signal sequences are as follows: Interleukin-2, Esterase-6, Adipokinetic hormone, Cuticle, pBMHPC-12, Chorion, Apolipophorin, and Sex Specific.

Interleukin-2 is a human signal sequence (for a T-cell growth factor) whose use with AaIT has previously been described (30). The adipokinetic hormone signal sequence (for a neuropeptide) is from Manduca sexta and fits the -3, -1 rule (29) well. The chorion signal sequence from Bombyx mori (for an eggshell structural protein) and the cuticl signal sequence of Drosophila melanogaster (for an exoskeletal protein) both secrete a large quantity of their associated mature proteins. The apolipophorin signal sequence from Manduca sexta (for a plasma lipid transport protein), the sex specific signal sequence of Bombyx mori (for a major adult plasma storage protein) and the pBMHPC-12 signal sequence from Bombyx mori (for a 30 kD larval plasma lipoprotein) all are selected because they are found in fat body cells and and each secrete a hemolymph protein. Finally, the esterase-6 signal sequence is used for the secretion of a serine hydrolase from Drosophila melanogaster. Each of these signal sequences except apoliphophorin complies with the -3,

-1 rule (29) for predicting the cleavage site.

The cDNA encoding each signal sequence can have either its native sequence or a codon optimized sequence generated as described above. Specific codon optimized signal sequences are constructed as described in Example 2 below.

5   The codon optimized signal sequences differ from the native sequences as follows:

pBMHPC-12 - 7 of 48 nucleotides (compare SEQ ID NO: 5 (codon optimized) with SEQ ID NO: 7 (native)); adipokinetic hormone - 6 of 57 nucleotides (compare SEQ ID NO: 9 (codon optimized) with SEQ ID NO: 11 (native)); apolipophorin - 14 of 69 nucleotides (compare SEQ ID NO: 13 (codon optimized) with SEQ ID NO: 15 (native)); chorion - 10 of 63 nucleotides (compare SEQ ID NO: 17 (codon optimized) with SEQ ID NO: 19

10   (native)); cuticle - 6 of 48 nucleotides (compare SEQ ID NO: 21 (codon optimized) with SEQ ID NO: 23 (native)); esterase-6 - 15 of 63 nucleotides (compare SEQ ID NO: 25 (codon optimized) with SEQ ID NO: 27 (native)); sex-specific - 15 of 45 nucleotides (compare SEQ ID NO: 29 (codon optimized) with SEQ ID NO: 31 (native)). However, the amino acids of the signal sequences encoded by the differing nucleic acid sequences are identical for both the codon optimized and native sequences.

15   An example of a codon optimized DNA sequence encoding a heterologous cuticle signal sequence joined to a codon optimized DNA sequence encoding AaIT and inserted into a baculovirus transfer vector is the transfer vector designated pAC0055.1 (see Examples 1, 2 and 4 below). Samples of an E. coli strain HB101 harboring this transfer vector pAC0055.1 were deposited by applicants on December 17, 1992 with the American Type Culture Collection, 12301 Parklawn Drive, Rockville, Maryland 20852, U.S.A., and have

20   been assigned ATCC accession number 69166. Using this deposited material, one of ordinary skill in the art can substitute a different signal sequence for the cuticle sequence contained in that plasmid.

Specifically, the first step is to construct a synthetic double stranded DNA fragment which has the following features: (i) a 5' terminal Bam HI-compatible cohesive end; (ii) a sequence encoding the ATG start codon and amino acid sequence of the new signal peptide; and (iii) a sequence encompassing the first 19

25   nucleotides in the top strand of the codon optimized AaIT gene and the first 23 nucleotides in the bottom strand. The 3' terminus of such a fragment contains a Sal I-compatible cohesive end. Substitution of this fragment for the corresponding Bam HI/Sal I fragment of pAC0055.1 is achieved by joining the following three fragments in the presence of-DNA ligase: (1) the Bam HI/Sal I synthetic fragment described above; (2) a Sal I/Kpn I fragment extending from the Sal I site at codons 6-7 in the codon optimized AaIT toxin gene to

30   the Kpn I site in the 3' flanking polyhedrin gene sequence; and (3) the largest Kpn I/Bam HI fragment contained in pAC0055.1. This fragment, which is derived from pVL985 (31), contains the pUC8 cloning vector and AcMNPV sequences which flank the 5, and 3' termini of the polyhedrin gene. Those skilled in the art will recognize that the resulting construct differs from pAC0055.1 only in the nature of the signal peptide.

35   Once recombinant viruses are prepared containing the codon optimized gene (see discussion above and Examples 1, 2, 4 and 5 below), they are tested to confirm the presence of the codon optimized AaIT gene. Because the codon optimized gene replaces the baculovirus polyhedrin gene, the recombinant viruses which carry the toxin gene are unable to form polyhedra and thus produce occlusion-negative plaques. Plaque purification is used to isolate recombinant viruses containing the AaIT gene from the

40   transfection supernatant by the method of Summers and Smith (25) (see Example 5).

Next, virus infected cells are assayed by dot blot hybridization for nucleic acids that hybridize to a radiolabelled DNA probe specific for the AaIT gene. Radioactivity is detected by autoradiography; a positive result confirms the presence of the AaIT gene in a virus isolate (see Example 6).

Methods similar to those described in Examples 1, 2, 4 and 5 below are used to construct a baculovirus

45   transfer vector containing the native AaIT gene and the native nucleic acid sequence encoding the native AaIT signal sequence, and then to prepare recombinant virus therefrom (see Examples 3-5 below). Polymerase chain reaction is used to verify that the recombinant viruses contain an insert of the correct size containing the AaIT gene (see Example 7 below). The recombinant viruses containing the native AaIT gene are used as positive controls in assays for the biological activity of recombinant viruses containing the

50   codon optimized AaIT gene with heterologous signal sequences.

Expression of the AaIT gene in insect cells infected with either the codon optimized or native AaIT-viruses is estimated by Northern blot analysis of total cellular RNA isolated from virus-infected cells (see Example 8 below). Analysis shows high levels of toxin-encoding RNA 24 hours post-infection (see Example 8).

55   As mentioned above, the baculoviruses infect a wide range of insects, but are not harmful to mammals. All species of insects examined are susceptible to paralysis caused by AaIT; however, mammals are not adversely affect d by the toxin.

The comparative biological activity of a wild-type baculovirus, a virus containing the native AaIT gene, and a virus containing the codon optimized AaIT gene (which may also contain a heterologous signal sequence) is assayed by two types of in vivo tests with insect larvae: an injection assay and a feeding assay.

In a preliminary assay, the culture medium and cell pellets (resuspended in buffer solution) obtained during the preparation of codon optimized AaIT-viral stocks are injected into Musca domestica (common house fly) larvae to determine whether those samples contain a detectable amount of biologically active AaIT.

Larvae are examined five seconds after injection for evidence of involuntary contraction of body segments. Results from the assay (see Table in Example 9 below) show that biologically active AaIT is detected in the cultured cells infected with 13 of 14 codon optimized AaIT-virus isolates with heterologous signal sequences (esterase-6, adipokinetic hormone and cuticle). The negative results are expected with the IL2-AaIT-virus constructs due to the presence of a frame shift mutation in the toxin gene coding region. The lack of detectable AaIT activity in any of the cell culture supernatants indicates that the level of biologically active secreted toxin is less than about 0.2 μg/ml.

A dose-response injection assay demonstrates that the insertion of the codon optimized AaIT gene enhances the performance of a baculovirus by reducing the time needed to kill a target insect species. As shown in Example 10 below and Figure 5, budded virus prepared from the codon optimized Cuticle-AaIT-AcMNPV construct and from the wild-type E2 strain of AcMNPV without the AaIT gene are injected into separate groups of mid-fourth instar larvae at doses of 10^2, 10^3 and 10^4 PFU per larva.

At each of the doses tested, the Cuticle-AaIT-AcMNPV kills its host faster than the wild-type AcMNPV. At 10^4 PFU, the LT_{50} for the wild-type virus is approximately 97 hours, whereas the corresponding LT_{50} for the Cuticle-AaIT AcMNPV is 67 hours. This result shows that insertion of the AaIT gene and the cuticle signal sequence into AcMNPV accelerates the speed of kill through the expression of biologically active toxin.

The injection assay protocol is repeated using older larvae (early fifth instar) with seven different codon optimized heterologous signal-AaIT-AcMNPV constructs, a native AaIT signal-native AaIT gene-AcMNPV construct and a wild-type E2 strain of AcMNPV without the AaIT gene. A dosage of 10^4 PFU of budded virus of each construct is injected into separate groups of larvae.

As described in Example 11 below, each of the codon optimized heterologous signal-AaIT-AcMNPV constructs (as well as the native AaIT signal-native AaIT gene-AcMNPV construct) kills its host faster than the wild-type AcMNPV. The LT_{50} for the wild-type virus is approximately 126 hours, whereas the corresponding LT_{50} for the seven heterologous signal-AaIT-AcMNPV constructs range from approximately 68-89 hours and the native AaIT-AcMNPV construct has an LT_{50} of approximately 74 hours. These results confirm the results of Example 10 that insertion of the AaIT gene and a heterologous signal sequence into AcMNPV accelerates the speed of kill through the expression of biologically active toxin.

In order to test the oral toxicity of these recombinant viruses, which are defective for the production of polyhedrin, polyhedra containing a mixture of wild-type and recombinant virions are prepared by co-infecting cells in culture with the recombinant AaIT-virus and a wild-type helper virus (such as the E2 strain of AcMNPV). This approach is made possible because one polyhedron (occlusion body) contains several hundred virions.

Accordingly, host cells are co-infected with various amounts of the recombinant AaIT-virus, as well as a wild-type virus. The resulting infected cells have polyhedra containing a mixture of wild-type and recombinant virions. As seen in Example 12 below, when the MOI of the wild-type virus is at least 2 PFU per cell, as the MOI of the recombinant virus increases, the percent of cells with viral occlusions and the average number of polyhedra per cell decrease significantly. Therefore, further co-occlusion studies are conducted with the occlusion-negative recombinant virus and the wild-type virus, each at an MOI of 3. This allows effective representation of the recombinant virions in the polyhedra at an acceptable level of polyhedron production.

Finally, an oral toxicity assay is conducted by feeding larvae a microdrop of insect diet containing a desired amount of PIBs. With the exception of the wild-type virus, each PIB contains a mixture of wild-type and recombinant virions. The recombinant virions may encode either the native AaIT gene (and native signal sequence), or the codon optimized gene linked to a heterologous signal sequence.

Larvae are then monitored for paralysis and death. The results of the assay are set forth in Example 13 and Figures 6-15.

All but one of the recombinant viruses demonstrate an earlier onset of morbidity than the wild-type AcMNPV (which lacks the AaIT gene). The exception is the AcMNPV construct containing the pBMHPC-12 signal sequence linked to the codon optimized sequence encoding AaIT, which performs approximately the

same as the wild-type AcMNPV. The recombinant viruses exhibit a characteristic paralytic response which is easily distinguished from the pathogenesis caused by the wild-type virus. The actual ratio of wild-type to recombinant virus in the polyhedra and in the infected insects is not analyzed.

5 In order that this invention may be better understood, the following examples are set forth. The examples are for the purpose of illustration only and are not to be construed as limiting the scope of the invention.

Examples

10 Standard molecular biology techniques are utilized according to the protocols described in Sambrook et al. (32).

Example 1

15 Determination of a Codon Optimized cDNA Sequence Encoding AaIT

The design of a codon optimized gene for AaIT begins with an attempt to reflect the codon usages of nuclear genes derived from the exact (or as closely related as possible) genome of the cell/organism that is intended to be used for recombinant protein expression. Here, however, adequate representation for both 20 lepidopteran and baculoviral gene sequences was not available to create a reliable codon usage table for these initial experiments.

Ikemura et al. have cautioned that reliable codon-choice patterns require the summation of codon frequencies from ten or more genes with varying functions (10,24). However, at the time of this invention, there was DNA sequence information from only two specialized proteins: AcMNPV polyhedrin and AcMNPV 25 p10 (22,23).

For this reason, Drosophila melanogaster is selected because its codon use tables are derived from 44 nuclear genes totalling 20,451 codons (11). These codon use tables are used to design the codon optimized genes encoding signal sequences and the AaIT toxin sequence of this invention.

Each full length signal peptide sequence is fused to the AaIT toxin peptide sequence. These amino acid 30 sequences are reverse-translated into a DNA sequence showing all possible nucleotide degeneracies (maximum ambiguity) using IntelliGenetics Suite™ software (version 1988; Palo Alto, CA). IntelliGenetics Suite™ software is used for all computer-assisted nucleic acid sequence analysis.

A list of definite and potential (because of codon degeneracies) restriction enzyme recognition sites is generated. Restriction enzyme sites critical for gene synthesis as well as for the convenience of additional 35 DNA manipulation are selected and preserved. For example, Bam HI and Ava I restriction enzyme sites are required for gene synthesis using Bluescript SK/KS vectors (Stratagene, LaJolla, CA). Sal I and Apa I restriction sites are desirable to permit flexibility for additional gene manipulation.

Using IntelliGenetics Suite™ software, a list recording the number of times each amino acid occurs in AaIT and each signal sequence is generated. Codons are assigned on the basis of the number of amino 40 acid residues present in the sequence to reflect the relative frequency of Drosophila melanogaster codon use (11).

For example, the cysteine codon frequency in Drosophila melanogaster is 76% for the sequence TGC and 24% for the sequence TGT. There are eight cysteine residues in the ADK signal-AaIT gene construct (all in the gene coding for the mature AaIT protein (SEQ ID NO: 3)). Hence, six codons are allocated as 45 TGC (75% of the residues) and two codons as TGT (25% of the residues). Based on this distribution, each cysteine codon is then assigned an exact, unambiguous sequence. Attention is given to alternating adjacent isocodons. For example, the two adjacent cysteine residues in the AaIT peptide (amino acids 37 and 38) are assigned the sequence TGT TGC to avoid assigning two identical codon sequnces sequentially.

This process is repeated for all twenty amino acids and the termination codon (although the termination 50 codon sequence TAA is not changed by this procedure). In addition, all critical restriction enzyme sites are preserved and unwanted sites are destroyed.

Flanking DNA sequences for the plasmid vectors as w II as the transfer vectors are fused to the completed gene sequences to confirm that there are no undesirable restriction enzyme sites at the splice-junction boundaries.

Example 2

Construction of Gene Cassettes Containing an Heterologous Signal Sequence Plus the Codon Optimized cDNA Sequence Encoding AaIT

5

Eight heterologous signal sequence-codon optimized AaIT toxin gene cassettes are synthesized and assembled in two pieces: A "B" fragment, unique for each construct, consisting of DNA coding for one of eight heterologous signal sequences, plus the amino terminal portion of the toxin coding region (common to all constructs), and an "A" fragment, which is the same for each construct and encodes the remainder of
10 the toxin coding region.

Each of fragments A and B is made by annealing a pair of oligomers containing a 15 bp overlap purchased from New England Biolabs (Beverly, MA). Sequenase™ 2.0, a DNA polymerase (United States Biochemical Corporation, Cleveland, OH), is used to complete the double stranded molecule, which contains the heterologous signal sequence plus the codon optimized cDNA sequence encoding AaIT. The

Figure 2 depicts the construction strategy for the AaIT gene cassette which contains the Drosophila melanogaster cuticle signal sequence. The remaining seven heterologous signal sequence-AaIT gene cassettes are constructed in the same way using the specific oligo for the signal sequence as indicated above.

In the first step, the signal sequence-specific oligo for the B fragment and the common B oligo are annealed and the single stranded regions are filled in using Sequenase™ 2.0. Each signal sequence-specific oligo consists of an identical 12 nucleotide upstream noncoding region containing the Bam HI site required for cloning, the coding region for the signal sequence, and the first 15 nucleotides encoding the first five amino-terminal amino acids of AaIT. This short piece of double stranded DNA is digested with Bam HI and Ava I and subcloned into pBluescript SK+ (Stratagene, LaJolla, CA) which had been digested with Xma I and Bam HI. Positive subclones are verified by the presence of a Pvu II fragment larger than the 445 bp fragment present in pBluescript SK+ alone. There is a single base pair mismatch between the overhangs for the Ava I and Xma I sites. Clones which have corrected this mismatch to regenerate the Aval site and lose the Xma I site are selected by the appropriate restriction enzyme digestions. In Figure 2, the resulting plasmid is designated pBS Cuticle B7.

To construct the A fragment encoding the bulk of the AaIT coding region, oligos E1 and E2 are annealed and Sequenase™ 2.0 is used to fill in the single stranded regions. This results in a double stranded molecule which contains an Ava I site at the 5' terminus and nested Bam HI and Asp 718 sites following the 3' end of the toxin coding region. The Bam HI and Asp 718 sites are introduced in order to facilitate cloning. Fragment A is then digested with Ava I and Asp 718. The fragment B-containing plasmid, pBS Cuticle B7, is also digested with Ava I and Asp 718 and Fragment A is subcloned into the digested plasmid. In the case of Figure 2, the resulting plasmid is designated pBS Cuticle-AaIT. Fragments A and B are joined at a unique Ava I site which is engineered into the AaIT sequence just for this purpose. After the ligation of fragment A into the fragment B-containing plasmid, the ligated DNA is used to transform competent DHα E. coli. Minipreps of plasmid DNA are prepared from the resulting bacterial colonies. Restriction enzyme analysis is used to determine which colonies contain the desired recombinant DNA. Further restriction enzyme analysis, followed by DNA sequencing, is used to confirm the integrity of the eight plasmids containing the codon optimized cDNA encoding AaIT.

Example 3

Construction of Gene Cassette Containing the Native cDNA Sequence Encoding AaIT

A gene cassette containing the native cDNA sequence encoding AaIT is constructed in two pieces, but in a manner different from the construction of the codon optimized genes of Example 2. Instead of using long oligos which have only a short r gion of overlap to construct the gene, sets of oligos which completely overlap ar used. A second difference in the manner of construction is necessitated because the native DNA s quences for both the AaIT signal sequence and coding region are used. No artificial restriction enzyme sites are engineer d into the DNA sequence. Therefore, a different method of joining the signal sequence and coding region of the AaIT gene is required. In this method, asymmetrically cutting restriction

enzymes are used to allow functionally separate regions of the gene to be neatly fused to each other. This allows one to mix and match premade regions in any future constructions. The sequences of the oligomers numbered 1-10 used for the construction of the native AaIT gene are provided in the list below:

In order to facilitate the cloning of the native AaIT toxin gene cassette, a modified Bluescript SK plasmid is generated. This vector designated pBS SK Bsm I has a Bgl II linker (CAGATCTG) inserted into the Nae I site located at 330bp on the Bluescript map. This linker insertion destroys the Nae I site. In addition this vector contains a modified polylinker as shown at the top in Figure 3. This modified plasmid is designated pBS SK Bsm I. This polylinker contains a Nae I site located adjacent to a Bsm I site, such that any sequence cloned into the Nae I site can be cleanly excised as a blunt-ended molecule by using the Bsm I restriction enzyme followed by filling in of the sticky end with the Klenow fragment of DNA polymerase I (Gibco/BRL, Gaithersburg, MD).

To construct the native signal sequence portion of the cassette, oligos 1 and 2 are annealed. When these two oligos are properly annealed, they contain a blunt 3' end and a Bam HI sticky end at the 5' terminus. The plasmid pBS SK Bsm I is digested with Bam HI and Nae I. The annealed oligos are then ligated to the digested plasmid. The resulting plasmid subclone is designated pBS GIII sig.

The coding region of the AaIT toxin is constructed as two pieces of DNA. The 5' ends of oligos 4, 5, 8 and 9 are phosphorylated using T4 kinase. Oligos 3, 6, 7 and 10 are left without a terminal phosphate. Two annealing reactions, followed by a ligation reaction using T4 DNA ligase (New England Biolabs, Beverly, MA) are carried out. Oligos 3, 4, 5, and 6, which encode the amino terminal portion of the AaIT toxin, are annealed and ligated as shown in Figure 3. Oligos 7, 8, 9 and 10, which encode the carboxy terminus of the AaIT toxin, are annealed and ligated as shown in Figure 3.

These two oligo fragments are purified by electrophoresis on a 2.5% low melt agarose gel (Bio-Rad, Richmond, CA) containing TAE (40 mM Tris-acetate, pH 7.8, 1 mM EDTA). When the fragments are sufficiently separated from contaminating fragments, they are cut out as gel slices and placed in individual tubes. The fragments are purified by phenol extraction as described in Sambrook et al. (32) with the following modifications: (1) Sodium chloride is added to the gel slices to a final concentration of 1.5 M prior to heating. No further addition of salt is required in the subsequent steps. (2) Only two phenol extractions are performed on the liquified and diluted gel slice prior to the ethanol precipitation.

The plasmid pBS GIII sig is digested with Bsm I and the sticky end is filled in and blunted with the Klenow fragment of DNA polymerase I (Gibco/BRL). As described above, this results in opening the plasmid at the last base pair of the signal sequence. The plasmid is then further digested with Eco RI. A three way ligation is then set up between the gel purified oligo fragments and the digested plasmid. Positive subclones are verified by restriction enzyme analysis, followed by DNA sequencing. One positive clone designated pBS GIII-AaIT contains the native signal sequence and full length native coding region of AaIT (Figure 3).

Example 4

Insertion of AaIT Gene Constructs into Baculovirus Transfer Vectors

The heterologous signal sequence-codon optimized AaIT gene cassettes of Example 2 are isolated as Bam HI fragments from the pBS signal-AaIT clones (see pBS Cuticle-AaIT example in Figure 2. These Bam HI fragments are subcloned into the pVL 985 baculovirus transfer vector DNA (31) which had been digested with Bam HI. Restriction enzyme analysis followed by sequencing of the insert is used to confirm the correct orientation and integrity of the pVL heterologous signal sequence-codon optimized AaIT clones.

For example, the plasmid pBS Cuticle-AaIT is subcloned into the pVL baculovirus transfer vector to yield the plasmid designated pAC0055.1.

The native AaIT gene cassette of Example 3 is isolated as a Bam HI to Eco RI fragment from the pBS GIII-AaIT clone (see Figure 3). These Bam HI to Eco RI fragments are subcloned into pVL 1393 baculovirus transfer vector DNA (33) which had been digested with Bam HI and Eco RI. Restriction enzyme analysis followed by sequencing of the insert is used to confirm the integrity of the pVL native AaIT clones.

Example 5

Generation of Recombinant Viruses Encoding AaIT

Recombinant viruses containing the native and codon optimized AaIT genes under the control of the AcMNPV polyhedrin promoter are generated by homologous DNA recombination in cultured Sf9 cells, as described by M. D. Summers and G. E. Smith (25). Sf9 cells (ATCC accession number CRL1711) are derivatives of the cell line designated Spodoptera frugiperda 21 (Sf21).

In this procedure, 2.0×10^6 Sf9 cells are seeded in a 60 mm culture dish in 5 ml of supplemented TNM-FH medium (Grace's insect medium (34) supplemented with 0.33% TC lactalbumin hydrolysate (Difco, Detroit, MI) and 0.33% TC yeastolate (Difco)), 10% fetal bovine serum, 0.1% Pluronic™ F-68 (Gibco/BRL)). Once the cells are firmly attached (2-16 hours), the medium is removed and replaced with 0.75 ml of Grace's insect medium supplemented with 10% fetal bovine serum. One microgram of AcMNPV (E2 strain) DNA is mixed with 2 µg of AaIT-transfer vector DNA from Example 4 in 0.75 ml of transfection buffer (25 mM HEPES, pH 7.05, 140 mM NaCl, 125 mM CaCl₂) and added dropwise to the cells. The cells are then incubated at 27°C for 4 hours. At the end of the incubation period, the transfection medium is removed and the cells are washed once with TNM-FH, fed again with 5 ml of supplemented TNM-FH, and placed in a 27°C incubator. After five days, the medium is removed from the cells, clarified by centrifugation for 10 minutes at 2000 rpm in a Beckman GPR centrifuge, and stored at 4°C. This constitutes the primary transfection supernatant.

Because the native and codon optimized AaIT genes replace the AcMNPV polyhedrin gene, the recombinant viruses which carry these toxin genes are unable to form polyhedra and, therefore, give rise to occlusion-negative plaques. Using this phenotype as a basis for identification, recombinant viruses containing the AaIT genes are isolated from the primary transfection supernatant by three rounds of plaque purification, using the plaque assay method of M. D. Summers and G. E. Smith (25).

In this procedure, $1.5-2.0 \times 10^6$ Sf9 cells are seeded into a 60 mm culture in supplemented TNM-FH. After the cells attach (2-16 hours), the medium is removed and replaced with 1 ml of supplemented TNM-FH containing 0.001-0.1% primary transfection supernatant. The virus is allowed to adsorb to the cells for 1-2 hours at 27°C, after which it is removed and replaced with 4 ml of molten (39°C) supplemented TNM-FH containing antibiotics and 1.5% low gelling temperature agarose. Once the agarose gels, the cells are transferred to an humidified 27°C incubator for 4-6 days. Occlusion-negative plaques are then identified by visual inspection under a stereo microscope and an agarose plug overlying each desired plaque is picked and diluted into 1 ml of supplemented TNM-FH.

The plaque purification procedure is repeated two additional times using 1-10% of the total virus recovered from each plaque. At the end of the third round, all of the virus recovered from a single plaque (i.e., 1 ml) is added to 2×10^6 Sf9 cells seeded in a 25 cm² flask and the flask is incubated at 27°C for 1-2 hours. The virus is then removed and replaced with 3 ml of supplemented TNM-FH, and the flask is returned to the incubator. At the end of 5 days, the supernatant, which is designated as the passage 1 or "P1" virus stock, is clarified by centrifugation for 10 minutes at 2000 rpm in a Beckman GPR centrifuge. Archive samples of the P1 stock are kept at -150°C, and the remainder of the virus is stored at 4°C.

Confirmation that the occlusion-negative viruses contain the desired AaIT gene is achieved by dot blot hybridization for the codon optimized AaIT-viruses (Example 6 below) and by polymerase chain reaction (PCR) for the native AaIT-virus (Example 7 below).

Example 6

Confirmation of Recombinant Viruses By Dot Blot Hybridization

To confirm the presence of the codon optimized AaIT gene in occlusion-negative viruses, virus-infected Sf9 cells from Example 5 are assayed by dot blot hybridization for nucleic acids that hybridize to a radiolabelled DNA probe specific for the AaIT gene. For this method, the cell pellets obtained during clarification of the viral P1 stocks are each resuspended in 1 ml Dulbecco's Phosphate Buffered Saline (D-PBS) and 100 µl aliquots are removed for hybridization. The cells are pelleted in an Eppendorf centrifuge at maximum speed for 15 seconds and then solubilized in 0.5 ml 0.5 M NaOH. After 10 minutes at room temperature, each sample is neutralized with 50 µl of 10 M NH₄OH. With the aid of a 96 well dot blot apparatus, 10 to 100 µl of the solubilized cell pellet is passed through a 3 mm diameter circle on a nitrocellulose membrane (Schleicher and Schuell BA85, (Keene, NH)) equilibrated with 1 M NH₄OH, 0.02 M NaOH. The wells of the blot apparatus are then washed with 0.5 ml 1 M NH₄OH, 0.02 M NaOH. The filter is removed from the apparatus, rinsed with 5 x SSPE (0.9 M NaCl, 50 mM NaH₂PO₄, 16.25 mM NaOH, 5 mM EDTA), and the nucleic acids are baked onto the membrane in a vacuum oven at 80°C for 2-3 hours. Before use, the membrane is incubated overnight at 42°C in prehybridization buffer (5 x SSPE, 50%(v/v) formamide, 0.2% SDS, 5 x Denhardt's (0.1% (w/v) polyvinylpyrrolidone, 0.1% (w/v) Ficoll 400™ (Pharmacia LKB, Piscataway, NJ), 0.1% (w/v) bovine serum albumin)).

The hybridization probe for codon optimized AaIT gene constructs is a ³²P-labeled double-stranded DNA prepared by annealing oligonucleotides E1 and E2 (described in Example 2) and then filling in the single-stranded regions with phage T7 DNA polymerase in the presence of ³²P-labeled dATP and

unlabelled dCTP, dGTP and TTP. The radiolabelled probe is denatured by heating and then diluted in hybridization buffer (prehybridization buffer supplemented with 100 μg/ml sheared and denatured salmon sperm DNA). The membrane is placed in the probe-containing hybridization buffer and incubated at 37°C for 16 hours. Unhybridized probe is then removed through four successive 20-30 minute washes: two at room temperature in 2 x SSPE, 0.2% SDS, and two at 65°C in 0.2 x SSPE, 0.2% SDS. Excess fluid is removed from the membrane and the membrane-bound radioactivity is detected by autoradiography using Kodak XAR medical X-ray film in the presence of an DuPont Cronex™ (Wilmington, DE) Lightning Plus intensifying screen. Using this assay, the presence of the AaIT gene is confirmed in 93% of the putative codon optimized AaIT-virus isolates examined.

Example 7

Confirmation of Recombinant Viruses Using the Polymerase Chain Reaction (PCR)

To verify that the putative native AaIT recombinant viruses contain an insert of the correct size, the distance between two known marker sites flanking the site of AaIT gene insertion is measured by PCR analysis of budded virus. The procedure is a modification of that described by B. Malitschek and M. Schartl (35). The primers for this analysis are located 84 to 110 bases upstream (5'-CAATATATAGTTGCT-GATATCATGGAG-3'; PVLForward) and 205 to 226 bases downstream (5'-GGATTTCCTTGAAGAGAGT-GAG-3'; PVLReverse) of the AcMNPV polyhedrin gene translational start site.

To prepare virus samples for analysis, 4 μl aliquots of each P1 stock, and of the wild-type AcMNPV E2 strain as a control, are each mixed in a GeneAmp tube (Perkin-Elmer/Cetus, Norwalk, CT) with 21 μl of Buffer A (10 mM Tris-HCl (pH 8.3), 40 mM KCl, 0.1 mg/ml gelatin, 0.45%(v/v) of Nonidet™ P40 (Shell Oil Co.), 0.45% (v/v) Tween™ 20 (ICI Americas)) supplemented with 200 μg/ml of a non-specific protease from Streptomyces griseus. Each tube is then incubated in a Perkin-Elmer/Cetus DNA Thermal Cycler running a single cycle three temperature program: (1) 55°C for 60 minutes, (2) 95°C for 12 minutes, and (3) soak at 4°C. The function of this program is to liberate the viral DNA from the budded virus and to destroy the pronase prior to the PCR amplification step.

Each sample is prepared for the amplification reaction by adding 24.5 μl of a solution containing 1 x Buffer A, 3.0 mM MgCl$_2$, 400 μM dATP, 400 μM dGTP, 400 μM dCTP, 400 μM TTP, 50 pmol primer 1 (PVLForward), 50 pmol primer 2 (PVLReverse). The PCR is initiated by adding 0.5 μl (2.5 units) of AmpliTaq DNA polymerase (Perkin-Elmer/Cetus) and starting a thermal cycler program consisting of 25-35 temperature cycles, wherein each cycle consists of (1) 1 minute at 94°C, (2) 1.5 minutes at 55°C, and (3) 2.5-3.0 minutes at 72°C. On the last cycle, the incubation time at 72°C is extended an additional 7 minutes, and the samples are then soaked at 4°C. An aliquot of each PCR reaction is then analyzed by gel electrophoresis in the presence of a suitable set of DNA size markers.

Each of four different putative native AaIT recombinant viruses tested by this method yields a single PCR product, the mobility of which is identical among the different samples and commensurate with the predicted size of 493 bp for the fragment being amplified. This fragment contains the primers flanking the site of gene insertion. Similarly, a single PCR product is obtained with the wild-type AcMNPV strain E2 virus, and its mobility is in good agreement with the predicted size of 337 bp.

Example 8

Analysis of RNA Levels in Virus-Infected Cells

Expression of the AaIT gene in Sf9 cells infected with the codon optimized and native AaIT-viruses is estimated by Northern blot analysis of total cellular RNA isolated from virus-infected cells. Total cell RNA is isolated by the guanidine thiocyanate/CsCl procedure (36,37).

In this procedure, Sf9 cells (5 x 10^7 in a 150 cm^2 flask) are infected with virus at an MOI of 5 PFU/cell and incubated at 27°C for 24 hours. The cells are then harvested by centrifugation (2000 rpm for 10 minutes in a Beckman GPR centrifuge) and the cell pellet is resuspended in 10 ml of 4 M guanidine thiocyanate solution (50% (w/v) guanidine thiocyanate, 0.5% (w/v) N-laurylsarcosine, 0.7% (v/v) β-mercaptoethanol, 25 mM sodium citrate (pH 7.0)). Total RNA is then partially purified by sedimentation through a 5.7 M CsCl, 0.1 M EDTA pad in a Beckman 70.1Ti rotor spun at 60,000 rpm for 4.5 hours. The RNA pellet is redissolved in 2 ml TES buffer (10 mM Tris-HCl (pH 7.5), 5 mM EDTA, 1% (w/v) SDS) and incubated for 5-10 minutes at 55°C to aid dissolution of the sample. The solution is then adjusted to 0.15 M NaCl and extracted once with water-saturated phenol. The aqueous phase is removed and the organic phase is re-

extracted twice more with 2 ml TES, 0.15 M NaCl. The aqueous phases are then combined and the RNA is precipitated with ethanol. The RNA pellet is redissolved in 2 ml H_2O and reprecipitated overnight at 4°C with an equal volume of 4 M LiCl. The pellet is then washed once with ice cold 2 M LiCl and redissolved in 0.5 ml H_2O. Residual LiCl is then removed by one last ethanol precipitation and the final pellet is redissolved in 0.2 ml H_2O. The RNA yield is determined by UV spectroscopy.

For Northern analysis 20 μg of each RNA is size fractionated by electrophoresis on a 1% agarose gel containing 2.7 M formaldehyde, 40 mM MOPS (4-morpholinepropanesulfonic acid) (pH 7.0), 10 mM sodium citrate, 1 mM EDTA. The RNA is then transferred by capillary blotting to a nitrocellulose membrane (Schleicher and Schuell BA85) in the presence of 20 x SSC (3 M NaCl, 0.3 M sodium citrate; adjusted to pH 7.0 with NaOH). The membrane is prehybridized briefly in hybridization buffer (50% (v/v) formamide, 0.9 M NaCl, 50 mM sodium phosphate (pH 7.0), 5 mM EDTA, 0.1% (w/v) SDS, 4 x Denhardt's, 0.4 mg/ml tRNA, 0.25 mg/ml calf thymus DNA) and then hybridized for 16 hours at 42°C in the same buffer containing a ^{32}P-labeled DNA probe prepared by random priming (38) a 464 bp Bam HI to Kpn I restriction fragment lying immediately 3' to the site of AaIT gene insertion in the AcMNPV polyhedrin gene. Following hybridization, unbound probe is removed by four successive 30 minute washes with 0.25 x SSC, 0.1% SDS at 65°C. A digitized image of the membrane-bound probe is produced by autoradiography using a Molecular Dynamics PhosphorImager™, and individual bands are quantified using ImageQuant™ v3.15 software (Molecular Dynamics, Sunnyvale, CA).

Figure 4 summarizes an analysis of AaIT/polyhedrin RNA levels in Sf9 cells infected with wild-type AcMNPV (labelled "wild-type") and with the codon optimized (labelled with the specific heterologous signal sequence) and native (labelled grp III AaIT) recombinant viruses. Only one species of polyhedrin-containing RNA is detected in each sample and all are of a size which is appropriate for the structure of the polyhedrin or AaIT/polyhedrin gene present in the virus. The amount of AaIT/polyhedrin RNA detected in the codon optimized AaIT-virus-infected cells ranges from 45-67% of the level of polyhedrin RNA accumulated in wild-type AcMNPV-infected cells. The corresponding value for native AaIT-virus-infected cells is 30%. This analysis shows that the AaIT/polyhedrin gene is correctly utilized and highly active in AaIT-virus-infected Sf9 cells.

Example 9

Production of Biologically Active AaIT in Virus-Infected Sf9 Cells

AaIT causes an acute excitatory (contractile) paralysis when 1 ng or more is injected into the dorsolateral area of Sarcophaga argyrostoma (flesh fly) larvae (39) A similar assay, using Musca domestica (house fly) larvae, is used to determine whether a detectable amount (1 ng) of biologically active AaIT is present in either the culture medium or cell pellets obtained during the preparation of the codon optimized AaIT viral P1 stocks.

To assay the culture medium, 2-6 μl of each P1 stock (600-1000 cell equivalents/μl) are injected into the dorsolateral area M. domestica larvae using a Hamilton syringe equipped with a 26 gauge needle. Larvae are examined five seconds after injection for evidence of involuntary contraction of body segments. Five larvae are assayed for each virus.

To assay AaIT activity in the cell pellets, the virus-infected Sf9 cells are washed once by centrifugation and the resuspended at a density of 30,000 cells per microliter in Dulbecco's phosphate buffered saline (D-PBS). An aliquot of the cell suspension is removed and frozen on dry ice and then thawed at 37°C three times in quick succession. Two microliters of the freeze/thaw lysate (i.e., 60,000 cell equivalents) are then injected into M. domestica larvae as described above and examined for acute contraction of body segments.

The table below summarizes the results obtained with an interleukin-2 signal-AaIT-virus mutant (containing a frame shift mutation) and three heterologous signal-codon optimized AaIT-virus isolates. Biologically active AaIT cannot be detected in any of the P1 stocks (cell culture supernatants) tested in this assay, indicating that the concentration of active toxin is in the range of 0.2 ng/μl or less in the supernatants. In contrast, AaIT is easily detected in 13 of 17 cell pellet lysat s. Three of the four negative lysates are derived from the mutant IL2-AaIT-virus isolates, which contain a frame shift mutation at position 265 in the toxin gene coding region. The other negative is obtained with isolate T9.4.1 (putative Cuticle-AaIT), which is negative by dot blot hybridization for the AaIT gene insert. The other four putative Cuticle-AaIT constructs give positive results, as do all nine of the Esterase-6-AaIT and adipokinetic hormone-AaIT constructs.

Isolate No.	AaIT Gene	Dot Blot Results	Supernatant	Cell Pellet
Mock infected	None	-	0/5	0/5
T6.1.1	IL2-AaIT	+	0/5	0/5
T6.2.1	[mutant]	+	0/5	0/5
T6.5.1		+	0/5	0/5

T9.5.1		+	0/5	5/5

Example 10

Analysis of Virus Performance by Injection into Larvae

To test whether insertion of the AaIT gene enhances AcMNPV performance, budded virus prepared from the codon optimized Cuticle-AaIT and from the wild-type E2 strain of AcMNPV without the AaIT gene are bioassayed by injection into mid-fourth instar Heliothis virescens (tobacco bud worm) larvae. Each virus is titered by the plaque assay method, as described by M. D. Summers and G. E. Smith (25), and then diluted to 2×10^7, 2×10^6, and 2×10^5 PFU/ml in TNM-FH medium supplemented with 0.5% (v/v) red dye number 5. Each larva is anesthetized with carbon dioxide for 2-5 minutes and then injected with 0.5 μl of diluted virus, using a Hamilton syringe equipped with a 26 gauge needle. The needle is inserted longitudinally between the last two prolegs and then moved anteriorly two to three body segments prior to injection. Following injection, each larva is inspected for the release of dye-stained hemolymph and discarded if sample loss is evident or suspected. The larvae are then stored at 27 °C in covered 4 cm^2 diet cells (one larva per cell) and inspected 2-3 times daily for evidence of morbidity or mortality. An individual is scored as moribund (positive response) if it is unable to right itself within 0.5-2 minutes after being turned on its back.

Figure 5 summarizes the results obtained when H. virescens larvae are injected with 10^2, 10^3 and 10^4 PFU of each virus. Forty-eight larvae are used for each virus dose. Eighty insects ("No Virus") are injected with TNM-FH alone as a negative control. The results show that the Cuticle-AaIT AcMNPV kills its host faster than the wild-type AcMNPV at each of the doses tested. At 10^4 PFU, the LT_{50} for the wild-type virus is approximately 97 hours, whereas the corresponding LT_{50} for the Cuticle-AaIT AcMNPV is 67 hours. Moreover, virtually all responding larva infected with Cuticle-AaIT, but not those infected with the wild-type AcMNPV, suffer from contractile paralysis prior to death. This result shows that insertion of the AaIT gene and the cuticle signal sequence into AcMNPV accelerates the speed of kill through the expression of biologically active toxin.

Example 11

Further Analysis of Virus Performance by Injection into Larvae

5   The procedure of Example 10 is repeated by injecting separate groups of early fifth instar Heliothis virescens larvae with 10^4 PFU of budded virus prepared from either the wild-type E2 strain of AcMNPV without the AaIT gene, a native AaIT signal-native AaIT gene-AcMNPV construct, or one of seven different codon optimized heterologous signal-AaIT-AcMNPV constructs. A given virus is administered to 32 larvae. Three separate assays are conducted. Larvae damaged by reason of the injection are not included in the
10   analysis. The data are pooled and the results are depicted in the following Table:

15

20

25

30

35

40

45

50

55

Bioassay Analysis of Recombinant AaIT-AcMNPV Isolates Injected Into 10d-11d *Heliothis virescens* larvae

Virus	Signal	n	df	L1(95%)	LT50	L2(95%)
AcMNPV-E2	N/A	81	5	123.8	126.0	128.2
AcMNPV-Es6/AaIT	Esterase-6	91	5	67.2	68.5	69.9
AcMNPV-ADK/AaIT	Adipokinetic	81	6	72.7	76.3	80.2
AcMNPV-Cut/AaIT	Cuticle	95	2	66.9	68.0	69.1
AcMNPV-Chor/AaIT	Chorion	89	7	77.3	79.0	80.8
AcMNPV-PBM/AaIT	pBmHPC-12	87	4	87.9	89.6	91.5
AcMNPV-Apo/AaIT	Apolipophorin III	92	4	85.7	87.4	89.1
AcMNPV-Sex/AaIT	SexSpecific	87	5	77.2	78.7	80.1
AcMNPV-AaIT/cDNA	AaH IT1	85	6	72.5	74.1	75.7

In the Table, "n" represents the total number of larvae from the three assays, "df" represents the degrees of freedom, "N/A" means not applicable, and "L1(95%)" and "L2(95%)" represent the confidence limits of the data, such that if the assay was rerun with an equal number of larvae, there would be a 95% confidence level that the LT_{50} would fall within the values shown for L1 and L2.

The results show that each of the codon optimized heterologous signal-AaIT-AcMNPV constructs (as well as the native AaIT signal-native AaIT gene-AcMNPV construct) kills its host faster than the wild-type AcMNPV. The LT_{50} for the wild-type virus is approximately 126 hours, whereas the corresponding LT_{50} for the seven heterologous signal-AaIT-AcMNPV constructs range from approximately 68-89 hours and the native AaIT-AcMNPV construct has an LT_{50} of approximately 74 hours. These results confirm the results of Example 10 that insertion of the AaIT gene and a heterologous signal sequence into AcMNPV accelerates the speed of kill through the expression of biologically active toxin.

Example 12

Co-Occlusion of Wild-Type and Occlusion-Negative Recombinant Viruses In Viral Polyhedra

Because the recombinant AaIT-viruses are defective for the production of polyhedrin, polyhedra containing a mixture of wild-type and recombinant virions are prepared by co-infecting Sf9 cells with the recombinant AaIT-virus and a wild-type helper virus (i.e., the E2 strain of AcMNPV). To determine the amount of each virus to use for co-infection, 2×10^7 Sf9 cells are seeded in a 150 cm² flask and infected with various amounts of the wild-type and recombinant viruses, each at a multiplicity of infection (MOI) of at least 1 plaque forming units (PFU) per cell. Four days later, the cells are counted and the percentage of cells with clearly discernible viral occlusions in the cell nucleus is determined by microscopic visualization. The total number of polyhedra is also determined by counting polyhedra in samples treated with 0.2% Triton X-100 and 2% (w/v) SDS. The results of one such analysis involving the co-occlusion of wild-type E2 AcMNPV and the cuticle-AaIT recombinant AcMNPV are summarized in the following Table:

Culture No.	MOI [WT:Cut-AaIT]	Total cells x 10^7	Percent of cells with occlusions	Total polyhedra x 10^8	Polyhedra per cell
1	10:0	2.15	94 %	4.10	19.0
2	10:1	1.85	92 %	3.65	19.7
3	10:2	2.30	89 %	3.30	14.3
4	5:5	1.85	74 %	2.15	11.6
5	2:10	2.00	36 %	0.55	2.75
6	2:20	2.10	23 %	0.12	0.57

These results demonstrate that even when the MOI of the wild-type virus is at least 2 PFU per cell, both the percentage of cells with viral polyhedra (occlusions) and the average number of polyhedra per cell decrease significantly as the MOI of the recombinant virus is increased. To maintain a large fraction of recombinant virions per polyhedron without making unacceptable sacrifices in the yield of polyhedra, all subsequent co-occlusion experiments are done with both viruses (i.e., wild-type and occlusion-negative recombinant) at an MOI of 3 each.

Example 13

Microdrop Bioassay to Measure the Oral Activity of Codon Optimized and Native Sequence Recombinant AaIT-Viruses Co-occluded into Polyhedra with Wild-Type AcMNPV

To examine the oral toxicity of the recombinant AcMNPV containing a codon optimized or native sequence encoding AaIT, each virus (with the exception of the IL-2/AaIT recombinant, which is not assayed) is co-occluded with wild-type AcMNPV into viral polyhedra (see Example 12) and fed to second instar Heliothis virescens larvae using a microdrop bioassay procedure as follows. Individual second instar Heliothis virescens larvae are transferred into empty assay wells containing a disk of prewetted filter paper. One larva is placed per well. The larvae are then stored at 26°C, 50% relative humidity for 12 to 20 hours (overnight).

The next day, a 15 ml aliquot of Stoneville insect diet (40) is heated to boiling. Five mls of water are added to the melted diet. This mixture is reheated to boiling and promptly centrifuged at low speed. Supernatant is removed and a few drops of food dye are added to the clarified supernatant as an aid to

visualize the diet. The molten diet is aliquoted into microfuge tubes, respun in a Beckman microfuge, and the clarified supernatant is transferred into new microfuge tubes. This molten diet is placed in a heat block at 54°C until needed.

After the diet cools to 54°C, the desired amount of PIBs is added. Typically, this ranges from 10 to 250 PIBs per µl. After mixing well, 1 µl drops of treated diet are aliquoted onto PARAFILM™ (American National Can, Greenwich, CT), where they harden. The hardened drops are quickly transferred to the wells containing the individual larvae, one drop per larva. The larvae are allowed to feed for 2 hours and those larvae which consume the entire microdrop are placed into a new assay well containing a standard amount of untreated Stoneville diet. Larvae are then placed at 26°C, 50% relative humidity, and monitored twice daily for paralysis and death. Paralysis is determined by rolling larvae onto their backs and observing for 30 seconds. If the larva remains on its back, it is considered moribund. Moribund larvae generally die during the 24 hours following diagnosis. The duration of the test is generally 8 days.

Larvae are inspected two to three times daily and scored for evidence of morbidity and mortality. Both dead and moribund larvae are scored as responding to the treatment. Figures 6-15 summarize the results obtained with each of the viruses.

With one exception, all of the recombinant viruses demonstrate an earlier onset of response than the wild-type AcMNPV (which lacks the AaIT gene). The exception is the AcMNPV construct containing the pBMHPC-12 signal sequence linked to the codon optimized cDNA encoding AaIT, which performs approximately the same as the wild-type AcMNPV. The actual ratio of wild-type to recombinant virus in the polyhedra and in the infected insects is not analyzed.

Claims

1. An isolated codon optimized nucleic acid sequence encoding Androctonus australis insect toxin (AaIT), wherein said sequence is that depicted in SEQ ID NO. 3.

2. An expression vector which contains the nucleic acid sequence of Claim 1.

3. The expression vector of Claim 2 wherein the expression vector is an insect virus.

4. The expression vector of Claim 3 wherein the insect virus is selected from the group consisting of nuclear polyhedrosis viruses, granulosis viruses, non-occluded viruses and entomopox viruses.

5. The expression vector of Claim 4 wherein the insect virus is a: (a) nuclear polyhedrosis virus selected from the group consisting of Lymantria dispar NPV (gypsy moth NPV), Autographa californica MNPV, Syngrapha falcifera NPV (celery looper NPV), Spodoptera litturalis NPV, Spodoptera frugiperda NPV, Heliothis armigera NPV, Mamestra brassicae NPV, Choristoneura fumiferana NPV, Trichoplusia ni NPV and Heliocoverpa zea NPV; (b) granulosis virus selected from the group consisting of Cydia pomonella GV (coddling moth GV), Pieris brassicae GV and Trichoplusia ni GV; (c) non-occluded virus selected from the group consisting of Orcytes rhinoceros NOV and Heliothis zea NOV; or (d) entomopox virus selected from the group consisting of Melolontha melonotha EPV, Amsacta moorei EPV, Locusta migratoria EPV, Melanoplus sanguinipes EPV, Schistocerca gregaria EPV, Aed s aegypti EPV and

Chironomus luridus EPV.

6. The expression vector of Claim 5 wherein the nuclear polyhedrosis virus is Autographa californica MNPV.

5

7. An expression vector which comprises the nucleic acid sequence of Claim 1 inserted into a baculovirus transfer vector.

8. A host cell transformed with the nucleic acid sequence of Claim 1.

10

9. The host cell of Claim 8 wherein the host cell is an insect cell.

10. A method of producing AaIT which comprises transforming or infecting a host cell with the nucleic acid sequence of Claim 1, and culturing the host cell under conditions which permit expression of said

15 nucleic acid sequence by the host cell.

11. The method of Claim 10 in which the host cell is an insect cell.

12. A method for protecting plants from damage from insects, which comprises delivering to said plant an

20 insect virus containing the codon optimized nucleic acid sequence of SEQ ID NO: 3.
